Spawning performance

Abstract

Temperature and photoperiod are known as the main stimuli of seasonal reproduction in fish. Turbot (*Scophthalmus maximus*) is a spring spawning teleost fish species with a promising aquaculture potential and high market value. This study was conducted to assess the effect of photoperiod manipulation on spawning time and spawning performance of turbot. A total of 28 mature turbot from the Black Sea population were subjected to manipulated photoperiod (a photoperiod regime that fish would naturally receive three months later) and natural photoperiod for almost a year. While the fish exposed to natural photoperiod spawned in May, the fish exposed to manipulated photoperiod spawned almost three months earlier compared to the natural photoperiod group. Reproductive and hatchery performance of the manipulated photoperiod and natural photoperiod groups were similar. It can be emphasized that photoperiod play an important role in accelerating maturation and spawning. The findings of this study could be implemented in the turbot aquaculture industry to advance production.

Introduction

Turbot, *Scophthalmus maximus*, is an economically important demersal fish species that widely distributed in the northeastern Atlantic Ocean, the Baltic Sea, the Mediterranean Sea, and the Black Sea (Firdin et al., 2020). Turbot spawns during the early summer from April to June in the Black Sea (Aydin et al., 2020; Aydin & Şahin, 2011), from March to May in the Adriatic Sea (Caputo et al., 2001), and from May to August in the North Sea (Jones, 1974) which coincides with several environmental factors. The variability of the spawning season is considered as a result of an evolutionary adaptation to various environments with different environmental conditions to maximize reproductive success and to guarantee the maximum survival of the offspring. The development of gametes is a complex multifactorial process. Like most of the fish species, turbot exhibit a seasonal cycle in the production of

gametes. Various strategies are being implemented to manipulate the spawning time of the fish. Environmental cues, such as water temperature cycles and photoperiod are two of the most important spawning stimuli in temperate fish species (Akhoundian et al., 2020; Altinok et al., 2020; Bromage et al., 2001; Oliveira et al., 2011).

Changes in photoperiod are mainly responsible for controlling the oocyte growth (Hansen et al., 1992), maturation (Imsland et al., 1997), and spawning time (Akhoundian et al., 2020). Imsland et al. (1995) and Turker (2005) assessed the effect of the photoperiod on growth of *S. maximus* and reported that the extended light period promotes the growth. Imsland et al. (2013) revealed that continuous light in long-term delays maturity in turbot whereas 16 hours light and 8 hours dark promotes growth and maturation. Turbot juveniles subjected to extended photoperiod resulted in faster growth compared to the fish reared at natural

photoperiod (Imstrand & Jonassen, 2003). The effect of modification in photoperiod on spawning time is well documented in numerous fish species including sea bass (*Dicentrarchus labrax*) (Carrillo et al., 1989), zebrafish (*Danio rerio*) (Abdollahpour et al., 2020), rainbow trout (*Oncorhynchus mykiss*) (Bromage et al., 1984), and Nile tilapia (*Oreochromis niloticus*) (Kilincceker & Kurt, 2010). To the best of our knowledge, no previous study has investigated the effect of photoperiod on the spawning time of turbot. In the present study, i) the effect of photoperiod manipulation on spawning time and ii) the effect of advanced spawning on sperm quality, egg quality, fertilization rate was assessed.

Material and Method

Fish and experimental design

The photoperiod manipulation experiment was conducted at the Central Fisheries Research Institute, Trabzon-Turkey. Turbot, *S. maximus*, used in the present study was originated from the Black Sea turbot population. To determine the influence of the photoperiod on the seasonal reproduction cycle of turbot, experimental group fish were exposed to manipulated photoperiod (MP group) and natural photoperiod (NP group) from June 1st until the reproduction season. Up to this date, the fish were reared on natural photoperiod. If the natural photoperiod cycle was continued all the fish were expected to be ready to spawn in May. MP group was exposed to the photoperiod regime that they would normally receive three months later. For instance, in June, MP group fish were subjected to the photoperiod regime that they would normally receive in September.

Mature 8-year-old turbots were randomly assigned to each group. Fourteen turbot, 7 females (57.76±1.35 cm, 4470.51±336.03 g) and 7 males (54.47±0.87 cm, 3198.18±467.08 g), were assigned to the NP group while another fourteen turbot, 7 females (59.11±1.34 cm, 4683.60±155.2 g) and 7 males (56.20±1.05 cm, 3252.22±172.4 g), were assigned to the MP group. Fish were tagged with passive integrated transponder (PIT) tags (Digital Angel Corporation, USA). Two 20 m³ octagonal concrete tanks (one for each group) with 15 m² of base area supplied with flow-through seawater were used in the experiments. Seawater taken from the depth of 40 meters with natural water temperature was continuously pumped to the system and the water exchange rate was set as 1000% (10 times a day) in each tank.

The tank of the MP group was isolated with light-proof sheets and illuminated by an artificial led light source, mounted 1.5 meters above the water surface. Light intensity on the water surface was set as 60 lux using bulbs (Philips, 80W, Natural White Light: 4000-4500K). Automated time clocks were adjusted weekly during the experiments to adjust the daylength. Natural photoperiod and manipulated photoperiod regimes are

given in Figure 1.

During the experiments, fish were fed once a day by hand to apparent satiation with red mullet, whiting, and anchovy. Water temperature was measured twice a day while salinity, pH, and dissolved oxygen concentrations were measured weekly (Figure 2). Water quality parameters were nearly identical in both tanks throughout the study.

Gamete collection, hormone injection, and spawning

The oocyte maturity stage was assessed from a sample of oocytes cannulated from the ovaries of females using a cannula. Oocytes were sampled twice a month starting from January 1st. Oocytes were measured and photographed under a light microscope (Eclipse E400, Nikon). Only females that produce oocytes with more than 400 µm in diameter were subjected to hormone injection. Female fish were induced with intramuscular injection of pellet des-Gly 10[D-Ala6]-LHRH-A (Sigma Aldrich) (100 µg/1000 g of body weight) according to Aydin and Okumus (2017).

Females were periodically checked for the sign of ovulation by palpation. Females that ready to spawn were weighed before and after collecting eggs to determine relative fecundity. Eggs were hand stripped into a dry plastic bowl and weighed. Eggs were fertilized with hand stripped milt obtained from two males in seawater (‰18 salinity) using the wet fertilization technique. Fertilized eggs were sterilized by incubating in PVP iodine solution (100 ppm) for 10 minutes and incubated in cylindrically conical incubation tanks. The number of eggs was estimated by counting a proportion of eggs. Egg diameters were measured under light microscope. The fertilization rate was estimated by sampling during the 2-64 cell stage. The hatching rate was estimated by sampling after hatching according to (Polat et al., 2018).

Sperm Analysis

For sperm analysis, milts were collected from mature fish with a syringe. Sperm spermatocrit rates were estimated by the microhematocrit technique. For this purpose, milt drawn in microhematocrit tubes were centrifuged at 12000 rpm for 10 minutes to separate the spermatozoa. To determine the sperm concentration, the collected sperm sample was drawn into a dilution pipette and diluted with distilled water (1/100). Sperm suspensions were loaded into a thoma cell counting chamber and counted by hemocytometer method.

Kinetic parameters (Motility, Curve speed, Linear speed, Linearity index, Beat frequency etc.) of the sperm samples were assessed by using a sperm class analyzer (SCA) CASA system with negative phase contrast (Ph-) microscopy (Nikon Eclipse CI). A digital camera attached to the microscope was used to capture images. Sperm samples loaded to chamber slides were activated with addition of seawater with ‰18 salinity. Sperm cell

tracks were photographed and analyzed. The osmolarity of milt samples was measured with Osmomat 3000 (Gonotec, Berlin). pH-Indicator papers (Merck) were used to measure the pH of milt samples. The viability duration of spermatozoa was assessed with Leja slide (Leja, Holland).

Statistical analysis

The normality of data and homogeneity of variances were tested by Shapiro-Wilk and Levene’s tests, respectively. The mean values of the parameters were compared using one-way analysis of variance (ANOVA). All statistical analyses were performed using R ver.4.0.3 (R Core Team, 2020) and significance level was considered as $P < 0.05$.

Results

Oocyte samples were collected from the MP group on January 20th and from the NP group on April 27th. A total of 620 oocytes were sampled from 12 females (6 natural photoperiods and 6 manipulated photoperiod). The average oocyte diameters of the females exposed to MP and NP were $399.04.50 \pm 2.75 \mu\text{m}$ and $401.14 \pm 3.32 \mu\text{m}$, respectively and found to be similar (ANOVA, $F_{1,618} = 0.237$, $P = 0.627$). The average of oocyte diameters of both groups exposed to MP ($t(312) = -0.347$, $P = 0.728$) and NP ($t(306) = 0.342$, $P = 0.732$) were equal to $400 \mu\text{m}$. Moreover, almost 50% of the sampled oocytes were greater than $400 \mu\text{m}$ in diameter (Figure 3). Thus, 6 females from each group were induced by hormone injection on January 25th (MP group) and on April 28th

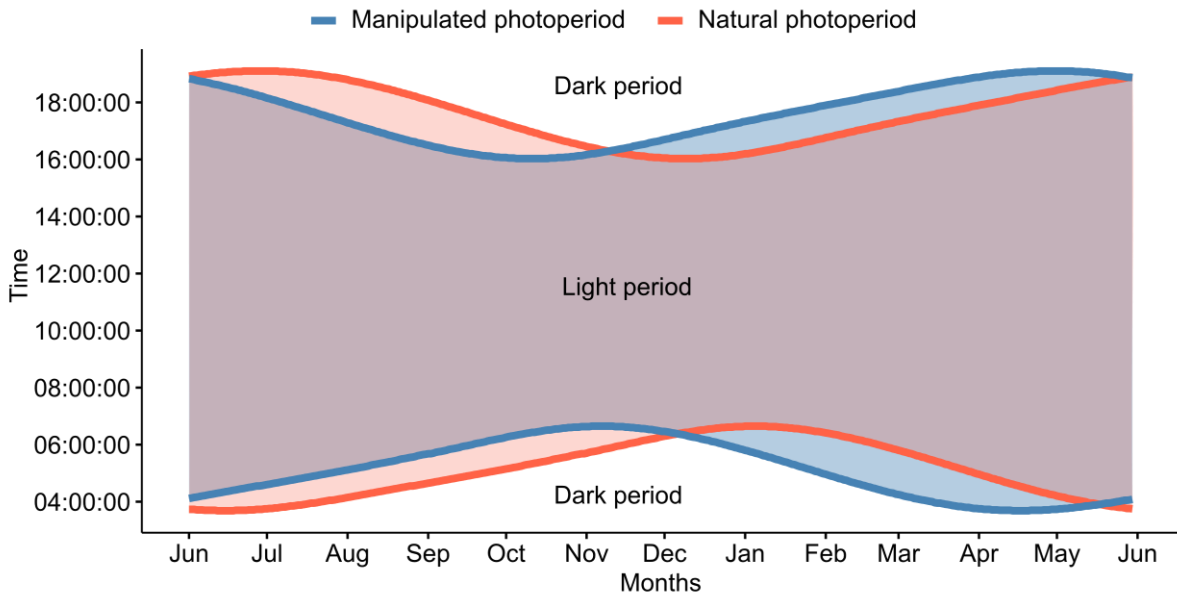

Figure 1. Natural (red) and Manipulated (blue) photoperiod regimes

Figure 2. Monthly changes in water temperature (A), dissolved oxygen (B), and pH (C).

(NP group). Concerning the spawning rhythms, four females in MP group positively responded induction and MP group begin spawning in February 10th (15 days post-induction). Females were stripped 8 to 17 days at 24 h intervals. Meanwhile, five females in the NP group positively responded to induction and the NP group begin spawning on May 12th (13 days post-induction). Females were stripped 9-17 days at 24 h intervals.

The average diameters of the stripped eggs of MP and NP groups were 1.22 ± 0.04 mm and 1.23 ± 0.03 mm, respectively. The average fecundity of MP and NP groups were $389,2410\pm 309,688$ and $412,0560\pm 146,808$,

respectively. The average relative fecundity of MP and NP groups were $826,850\pm 56$ and $903,903\pm 25$, respectively. The average fertilization rate, hatching rate, and abnormal larvae hatching rate of the MP group were $75.92\pm 2.7\%$, $82.3\pm 3.1\%$, and $4.42\pm 0.06\%$, respectively. The average fertilization rate, hatching rate, and abnormal larvae hatching rate of the NP group were $78.11\pm 1.89\%$, $86.37\pm 2.34\%$, and 3.02 ± 0.22 percent, respectively. The mentioned measurements were tested by one-way ANOVA and no significant differences were determined between the groups (Figure 4).

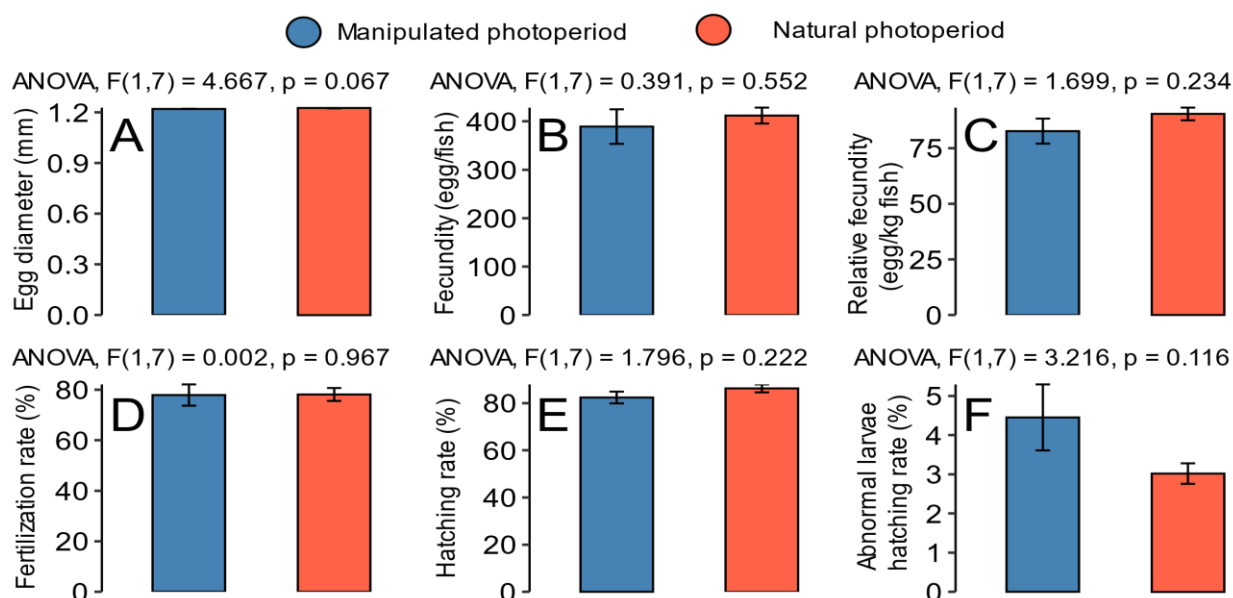

Figure 4. Comparison of egg diameter (A), fecundity (B), relative fecundity (C), fertilization rate (D), hatching rate (E), and abnormal larvae hatching rate (F) of the MP and NP groups

Milt was successfully obtained from five fish from the MP group and seven fish from the NP group. The average pH of the milt of MP and NP groups was 7.10 ± 0.04 and 7.16 ± 0.06 , respectively. The average sperm density of MP and NP groups were $2.18 \pm 0.15 \times 10^9/\text{ml}$ and $2.24 \pm 0.10 \times 10^9/\text{ml}$, respectively. The average sperm volume of MP and NP groups was 1.92 ± 0.26 ml and 2.41 ± 0.17 ml, respectively. The average spermatocrit context of MP and NP groups was $41.7 \pm 4.42\%$ and $41.9 \pm 3.58\%$, respectively. The average sperm osmolarity of MP and NP groups was 320.00 ± 2.09 mOsm/kg and 317.33 ± 4.43 mOsm/kg, respectively. There was no statistical difference between the MP and NP groups in terms of the mentioned sperm measurements (Figure 5). Additional and detailed kinetic sperm parameters are given in Table 1.

Discussion

Positive effects of photoperiod manipulation on maturation have been recorded in several species (Carrillo et al., 1989; Hansen et al., 1992; Macquarrie et al., 1978) including turbot (Imstrand et al., 2013; Imstrand & Jonassen, 2003). Imstrand and Jonassen (2003) found that maturation in juvenile turbot is related to photoperiod regime and lower maturation was observed in males that exposed to continuous or extended light. Imstrand et al (2013) revealed that continuous light delays maturity in juvenile turbot. While there are handful of studies on the effect of photoperiod manipulation on maturity, the effect of photoperiod manipulation on spawning season and spawning performance of turbot is unknown. This effect

of photoperiod manipulation on spawning season and spawning performance of turbot is evaluated for the first time in the study.

Turbot spawn in early summer (between April to June) in the Black Sea (41°N). In photoperiod manipulated group, fish spawned almost three months earlier compared to the natural photoperiod group which indicates the importance of the photoperiod on spawning season. The natural photoperiod group, that considered as the control group, spawned in May, which is reflecting the natural trend in the Black Sea.

Six out of 7 females from each group produced oocytes with the desired diameter ($\geq 400 \mu\text{m}$). According to Çiftçi *et al.* (2002) females with an average oocyte diameter of $400 \mu\text{m}$ can be used for spawning procedures with hormone injection. Four out of six females from MP and five out of 6 females from NP positively responded to ovulation induction and used in spawning. Nonresponse to ovulation induction among broodstock is a common phenomenon in turbot (Mugnier *et al.*, 2000). Individual differences between groups, rather than photoperiod manipulation could be the main result behind the differences in the number of positively induced individuals. The stripped egg size of the groups was similar. Egg size similarity between hormone induced and control groups was previously reported (Mugnier *et al.*, 2000).

Mcevoy and Mcevoy (1991) reported that the mean egg diameters of turbot reduce with each batch under constant water temperature. Bromley *et al.* (1986) found a negative relationship between egg diameter and water temperature at the time of spawning. However, in this study, almost identical average egg sizes were recorded for both NP and MP groups. Shortened spawning duration and water temperature appeared to be not related to the egg size. However, it is worth mentioning that female fish used in this study did not subject to hormone induction in the previous spawning season.

Usage of outdoor tanks and sea cages in initial trials of turbot culture has been suppressed for being not viable. Intensive rearing conditions under a controlled environment are being applied in both the grow-out and on-growing phase of turbot. Indoor facilities with heated water and mostly with re-circulation systems are now in use in most of the turbot farms (Peron-Le, 2002). Photoperiod manipulation in indoor facilities is easier and applicable. Thus, the result of this study may have implications in the turbot aquaculture industry.

Conclusion

The effect of the manipulated photoperiod on the spawning time, egg, and sperm production of turbot *S. maximus* were assessed. Previous studies reported that the manipulated photoperiod has positive effect on growth and maturity of turbot. This study reveals that spawning time of the turbot can be pushed forward by manipulating the natural daylength. The fish exposed to

manipulated photoperiod exhibited similar reproductive and hatchery performance with the ones held in natural photoperiod. To this respect, the manipulated photoperiod can be used for early hatchery rearing in the production process. Nevertheless, comprehensive research is needed to understand effect of photoperiod along with different light intensities on the hatchery performance, embryonic and pre-larval development, and metamorphosis.
